ABSTRACT

It is largely unknown how the runtime of evolutionary algorithms depends on fitness landscape characteristics for broad classes of problems. Runtime guarantees for complex and multi-modal problems where EAs are typically applied are rarely available.

We present a parameterised problem class SparselocalOpt_{\alpha,\varepsilon}, where the class with parameters $\alpha, \varepsilon \in [0,1]$ contains all fitness landscapes with deceptive regions of sparsity ε and fitness valleys of density α . We study how the runtime of EAs depends on these fitness landscape parameters.

We find that for any constant density and sparsity $\alpha, \varepsilon \in (0,1)$, SparselocalOpt $_{\alpha,\varepsilon}$ has exponential elitist $(\mu+\lambda)$ black-box complexity, implying that a wide range of elitist EAs fail even for mildly deceptive and multi-modal landscapes. In contrast, we derive a set of sufficient conditions for non-elitist EAs to optimise any problem in SparselocalOpt $_{\alpha,\varepsilon}$ in expected polynomial time for broad values of α and ε . These conditions can be satisfied for tournament selection and linear ranking selection, but not for (μ,λ) -selection.

1 INTRODUCTION

Non-elitist evolutionary algorithms (EAs) have been proved to be competitive with the elitist ones on a variety of benchmark functions [3, 9], and to perform well in complex settings such as under incomplete information of the objective function [9], under noise

[8] or in dynamic optimisation [7]. Yet it remains an open question whether a pure non-elitist EA on some significant problem classes can efficiently escape a local optima region once the latter has been discovered. This is a fundamental question as non-elitism means the ability to at some point during the search forget some good solutions, albeit local optima, in favour of exploration. Showing rigorously that a non-elitist EA can escape a local optimum while elitist EAs get stuck has been a fundamental open problem in evolutionary computation. In the rest of the section, we will discuss the previous studies that are related to this open problem and describe the contribution of this paper.

1.1 Previous Work

It was shown in [29] that the use of bit-wise mutation is crucial for the (1+1) EA, in contrast to the fixed mutation of the Randomised Local Search (RLS), to find the global/local optimum of the LongPath function in expected polynomial time. Later, it was shown in [13] that even the (1+1) EA requires a super-polynomial time to optimise the modified function LongPath \sqrt{n} .

Crossover has been a long-time suggested operator that allows faster escaping from local optima [20]. Using JUMP as the benchmark function where the performance of mutation-only EAs is restricted to $\Omega(n^k)$ with k being the Hamming distance from the global optimum from the local optima, in [6] it was shown that the interplay between mutation and crossover operators can increase the diversity of the population in $(\mu+1)$ EA, hence enabling the algorithm to leave the local optima in a shorter time. An $\Omega(\sqrt{n})$ speed-up in the overall expected runtime is proved for the standard mutation rate 1/n, and it is increased to $\Omega(n)$ with mutation rate 2/n. In the same line of research, it was shown in [5] that artificially enforcing population diversity with common mechanisms found in Evolutionary Computing (EC) literature enables the $(\mu+1)$ EA to escape the local optima faster and hence optimise JUMP efficiently. Similar arguments relying on the impact of various operators found in EC, e.g. ageing, tabu, hypermutation, to population diversity allowed the local performance proofs of these operators [26, 31, 38].

Like the theoretical studies of elitist EAs, the research on the local performance of non-elitist EAs started with simple populations that consist of a single individual. Popular algorithms in this category are Metropolis, and Simulated Annealing (SA). It was shown [17] that the convergence of SA to the global optimum depends on the temperature schedule and on the depth of the deepest local optimum which is not the global one. It was also proved [33] that SA can beat Metropolis on a class of minimum spanning tree instances.

The $(1, \lambda)$ EA was compared with the $(1+\lambda)$ EA on the CLIFF function in [21], where the $(1, \lambda)$ EA is proved to outperform the

 $(1 + \lambda)$ EA when lambda is logarithmic in n. However, the $(1, \lambda)$ EA with smaller λ is shown to be inefficient on any pseudo-Boolean function with a unique optimum.

More recently, the scheme of Strong Selection Weak Mutation (SSWM), which is well-studied in Population Genetics, was introduced as a search algorithm for EC in [27]. The authors proved a speed-up of $e^{\Omega(d)}$ of SSWM over the base expected runtime $\Theta(n^d)$ of the (1+1) EA on the CLIFF function, here d is both the height of the local optima and the distance from them to the global optimum.

The *elitist* $(\mu+\lambda)$ -*black-box model* introduced in [12] was used to study inherent performance limits of EAs using (certain) elitist selection mechanisms. The model covers any algorithm which bases its decisions solely on the μ best found solutions found so far. It was shown that some problem-tailored, non-elitist EAs can optimise efficiently some problem classes which have exponential elitist black-box complexity. However, these tailored EAs are unlikely to perform well on other problem classes, so [12] does not answer whether standard non-elitist EAs can outperform elitist EAs.

Based on the construction of LongPath, the ValleyPath function was introduced in [25]. It was shown that the non-elitist algorithms with population of size 1, such as the SSWM and Metropolis, are able to cross a valley of deceptive fitness, and their ability to escape the current local optimum depends on the depth of the valley. This is in contrast to the (1+1) EA in which case the ability to escape crucially depends on the width of the valley.

In the experimental analysis of meta-heuristics, also a lot of attention has been given to the relationship between the structure of the fitness landscape and the performance of EAs (see e.g. [19, 28]), especially the ones with a population of a single individual, elitist and non-elitist. In particular, in [32] it was demonstrated that the presence of multiple sub-optimal funnels in fitness landscapes contributes to lower success for Randomised Local Search and SA.

Related to our work, a simple modification of the LeadingOnes function was studied in [10], where a single peak/local optimum at height m is placed at the all zeroes bitstring. Under the assumption of the initial population on the peak, a normal $(\mu+\lambda)$ EA obviously needs $e^{\Omega(m)}$ expected evaluations to optimise the function. On the other hand, the (μ,λ) EA with two possibilities of mutation parameter embedded and co-evolving with each individual is shown to optimise the function in $O(n\lambda \log \lambda + n^2)$ expected evaluations. Furthermore, the same framework of self-adaption for non-elitist populations has been also adopted in [2] to include more possibilities for the mutation parameter, allowing the handling of optimisation problems with unknown solution length efficiently.

A common feature of such positive results for the non-elitist EAs is that the mutation rate has to be set below but pretty close to a known limit, above which they are inefficient in optimising functions with unique optimum [22]. This limit, called the *error threshold*, is studied in both evolutionary computing [11, 22, 23], population genetics [34], and virology [1]. The experimental results in [4] have also indicated that setting the mutation rate close to the error threshold allows the EAs with tournament selection to succeed on some benchmarks of the Set Cover problem.

In contrast to the upper bounds on runtime of the non-elitist EAs [3, 10, 23], the tight analysis of the (μ, λ) EA runtime on JUMP, obtained in [11], indicates that there is no benefit of the non-elitist

comma selection with any setting of mutation rate on this function with multiple local optima.

The first exponential separation between the elitist $(\mu+\lambda)$ EA and a non-elitist, population-based EA was shown for the Funnel problem [4]. This result holds for 3-tournament selection, and contrasts the conclusions from [11], indicating that results for (μ, λ) -selection cannot be extrapolated to other non-elitist selection mechanisms. In fact, it was shown in [4] that the non-elitist (μ,λ) -EA has exponential expected runtime on Funnel, assuming that the μ best individuals of the initial population are in the basin of attraction of a local optimum and close to it. The (μ,λ) EA considered in the last negative result is indeed a non-elitist algorithm, except that the comma selection is used instead of tournament or linear ranking selection. The intuition to the difference between (μ, λ) -selection and non-elitist selection mechanisms like tournament selection comes from the following difference in selection probabilities. Let P be a population of size λ and sorted in a descending order according to fitness, and define $\beta(\gamma, P)$ to be the probability of selecting an individual at least as good as the $[\gamma\lambda]$ -ranked individual of P, see e.g. [23]. In the case of (μ, λ) -selection, before reaching 1.0, $\beta(\gamma, P)$ is essentially linear [23]: $\beta(\gamma, P) = \gamma \lambda / \mu$ if $\gamma \le \mu / \lambda$. The advantage that tournament has over the comma selection is the non-linearity of its $\beta(\gamma, P)$, namely $\beta(\gamma, P) = 1 - (1 - \gamma)^k$, [23] where k is the tournament size.

Indeed, let us make a simplistic assumption that p_0 is a constant representing the probability of making copies of some high quality solution x, which could be a promising new incumbent or just a local optimum causing a stagnation, and assume that a γ -fraction of the population are copies of x. If x is a promising new incumbent, we want this fraction to grow, which requires that $\beta(\gamma,P)p_0 > \gamma$ when γ is small. If x is just a local optimum, we also want the fraction to not grow too large so that the remaining part of the population has some chance to reproduce, this requires $\beta(\gamma,P)p_0 < \gamma$ when γ is too large. It is easy to see that within the co-domain [0,1) the $\beta(\gamma,P)$ mentioned above for tournament selection can display both properties: it can be set to stay above the function $f(\gamma) = \gamma/p_0$ up to some point, then afterwards to move below f. The linear function of comma selection on the other hand can only display either one of the two properties.

1.2 Contributions of this Paper

We study how the runtime of evolutionary algorithms depend on properties of the fitness landscape [30, 36]. We classify fitness landscapes based on the *sparsity* of deceptive regions ("local optima") and the *density* of surrounding "fitness valleys" (see Defs. 1 and 2).

For any parameters $\alpha, \varepsilon \in [0,1]$ and fitness function f, we say that f belongs to the problem class SparseLocalOpt $_{\alpha,\varepsilon}$ if all its deceptive regions are ε -sparse, and all its fitness valleys are α -dense (Definition 4). Thus, the parameters induce a problem hierarchy: whenever $0 \le \alpha' \le \alpha \le 1$ and $0 \le \varepsilon \le \varepsilon' \le 1$,

 $\mathsf{SparseLocalOpt}_{\alpha,\varepsilon}\subseteq \mathsf{SparseLocalOpt}_{\alpha',\varepsilon'}.$

Intuitively, increasing the parameter ε relaxes the sparsity requirement for the deceptive regions, and decreasing the parameter α relaxes the density requirement on the fitness valleys. In the limit when $\alpha=0$ and $\varepsilon=1$, the problem class contains almost any function (barring a technical condition (SP2) from Def. 2). In the other

limit, when $\alpha=1$ and $\varepsilon=0$, the class contains only completely non-deceptive problems, such as OneMax and LeadingOnes.

We prove the following runtime results with respect to this classification:

- SparselocalOpt $_{\alpha,\varepsilon}$ has an exponential *elitist* black box complexity (in the sense of [12]) for any constant levels of denseness α and sparsity ε , which we demonstrate on the BBFunnel problem sub-class. This negative result (Theorem 10) implies that a large set of elitist EAs, including those with one-point, bit-wise or heavy-tailed mutation, crossover etc. are inefficient on problems with even mild degrees of deception.
- Standard diversity mechanisms do not help the elitist (μ+1) GA optimise BBFunnel efficiently (Theorem 11).
- Non-elitist EAs with bit-wise mutation have expected polynomial runtime on SparseLocalOpt $_{\alpha,\varepsilon}$, given the appropriate values of α,ε , and selection and mutation parameters (Theorem 15). In particular, this applies to EAs with 3-tournament selection and linear ranking selection.
- The non-elitist (μ,λ) EA has an exponential expected runtime on the BBFunnel problem, assuming the standard initialisation of the EA population (Theorem 21). This standard assumption improves the negative result on (μ,λ) EA from [4].

2 PRELIMINARIES

The natural and base-2 logarithms are denoted $\ln(\cdot)$, and $\log(\cdot)$ respectively. $\mathbb N$ is the set of natural numbers. For any $n \in \mathbb N$, define $[n] := \{1, \dots, n\}$. The Iverson bracket is denoted by $[\cdot]$. The *Hamming distance* is denoted by $H(\cdot, \cdot)$. The *Hamming sphere* with radius $r \in [n]$ around a bitstring $x \in \{0, 1\}^n$ is defined by $S_r(x) := \{y \in \{0, 1\}^n \mid H(x, y) = r\}$. Clearly, $|S_r(x)| = \binom{n}{r}$.

Given a partition of a search space X into m ordered "levels" (A_1, \ldots, A_m) , we define $A_{\geq j} := \bigcup_{i=1}^m A_i$.

Given two bitstrings x and y, we let $x \cdot y$ and xy denote the concatenated bitstrings.

A *simple path* is any sequence of bitstrings $x_1, \ldots, x_\ell \in \{0, 1\}^m$, where for all $i, j \in [\ell]$, if $x_i = x_j$ then i = j (i. e. uniqueness of each string), and for every $i \in [\ell - 1]$, $H(x_i, x_{i+1}) = 1$ (i. e. consecutively separated by a Hamming distance of 1) [14]. Clearly, simple paths contain no cycles.

Some definitions use the standard pseudo-Boolean functions OneMax(x) := Om(x) := $\sum_{i=1}^{n} x_i$, and y, Lo $_y(x)$:= $\sum_{i=1}^{n} \prod_{j=1}^{n} [x_j = y_j]$ for a bitstring y.

For an event E and random variable X, we use the notation $E[X;E] := E[X1_E]$, using the random variable $1_E(\omega) := [\omega \in E]$ (see e.g. Section 6.3 in [35]).

A *population* is a vector $P \in X^{\lambda}$, the *i*-th individual of P is denoted P(i). Given $x \in X$, define $H(x, P) := \min_{j \in [|P|]} \{H(P(j), x)\}$, and for $A \subseteq X$, we let $|P \cap A| := |\{i \mid P(i) \in A\}|$, i.e. the number of individuals of P belonging to A.

All non-elitist EAs with *unary variation operators* can be cast in the framework of Algorithm 1 [9]. A new population P_{t+1} is generated by independently sampling λ individuals from an existing population P_t according to a selection mechanism p_{sel} , then by perturbing each of the selected individuals with a unary variation operator p_{mut} . The algorithm in turn is a special case of a more

general framework of Algorithm 2, for which the *level-based theo- rem* [3] was developed. To prove the positive result in this paper, we derive a variant of that theorem, i.e. see Theorem 12.

We will characterise selection mechanisms in the following way. If the individuals in a population P are ordered by decreasing fitness such that that $f(P(1)) \geq f(P(2)) \geq \cdots \geq f(P(\lambda))$, then $\beta(\psi, \gamma, P)$ where $0 \leq \psi \leq \gamma \leq 1$ is the probability that the selection mechanism chooses an individual ranked between $\lceil \psi \lambda \rceil$ and $\lceil \gamma \lambda \rceil$ in the population. We omit the symbol P from the notation when the population is clear from the context. Note also that the 2-argument variant of the definition of β , such as the one used in [23] or in our introduction, is the special case of the above notation with $\psi=0$.

Algorithm 1 Non-elitist EA with unary variation operator [9]

Require: Initial population $P_0 \in \mathcal{X}^{\lambda}$ where $\mathcal{X} = \{0, 1\}^n$, and a mutation rate parameter $\chi \in [0, n]$.

- 1: **for** $t \in \mathbb{N}$ until a termination cond. is met **do**
- 2: **for** i = 1 to λ **do**
- Sample $I_t(i) \sim p_{sel}(P_t)$, and set $x := P_t(I_t(i))$.
- Sample $x' \sim p_{\text{mut}}(x, \chi)$, and set $P_{t+1}(i) := x'$.
- 5: end for
- 6: end for

Algorithm 2 Population-based algorithm [3].

Require: A finite state space X, and population size $\lambda \in \mathbb{N}$, a mapping D from X^{λ} to the space of prob. dist. over X, and an initial population $P_0 \in X^{\lambda}$.

- 1: **for** t = 0, 1, 2, ... until termination condition met **do**
- 2: Sample $P_{t+1}(i) \sim D(P_t)$ independently for all $i \in [\lambda]$.
- 3: end for

Algorithm 3 (μ + λ) elitist black-box algorithm [12], f is unknown.

- 1: $P_0 \leftarrow \emptyset$
- 2: **for** $i \in [\mu]$ **do**
- 3: Depending only on the multiset P_0 and the ranking $\rho(P_0, f)$ of P_0 induced by f, choose a probability distribution $p^{(i)}$ over $\{0,1\}^n$ and sample $x^{(i)}$ according to $p^{(i)}$
- 4: $P_0 \leftarrow P_0 \cup \{x^{(i)}\}$
- 5: end for
- 6: **for** $t = 0, 1, 2, \dots$ **do**
- 7: Depending only on the multiset P_t and the ranking $\rho(P_t, f)$ of P_t induced by f choose a probability distribution $p^{(t)}$ on $(\{0,1\}^n)_{i=1}^{\lambda}$ and sample $(y^{(1)}, \dots, y^{(\lambda)})$ according to $p^{(t)}$
- 8: $P_{t+1} \leftarrow P_t \cup \{y^{(1)}, \dots, y^{(\lambda)}\}$
- 9: **for** $i \in [\lambda]$ **do**
- 10: Select $x \in \operatorname{argmin} f(P_{t+1})$ and update $P_{t+1} \leftarrow P_{t+1} \setminus \{x\}$
- 11: end for
- 12: end for

In k-tournament selection, p_{sel} returns $argmax_{i \in S} f(P_t(i))$ where S is a set of k random numbers is drawn independently and uniformly from $[\lambda]$. The corresponding β is non-linear, with $\beta(\gamma_1, \gamma_2) = \beta(\gamma_1, \gamma_2)$

 $(1-\gamma_1)^k-(1-\gamma_2)^k$. In (μ,λ) -selection (comma-selection), the set of indices $S=[\lambda]$ is first sorted according to fitness, then $p_{\rm sel}$ returns S[i] where $i\sim {\rm Unif}([\mu])$. In this case, before reaching 1.0, β is a linear function [23] satisfying $\beta(\psi,\psi+\gamma)=\gamma\lambda/\mu$ if $(\psi+\gamma)\leq\mu/\lambda$. Linear ranking selection (Corollary 17) is defined in [16].

We consider the standard *bitwise mutation operator* as p_{mut} and it is configured by a parameter $\chi \in (0, n/2]$ so that for any pair of bitstrings $x, x' \in \{0, 1\}^n$, the probability of obtaining x' from x is $\Pr(x' = p_{\text{mut}}(x, \chi)) = (\chi/n)^{\text{H}(x, x')} (1 - \chi/n)^{n-\text{H}(x, x')}$.

The elitist black-box model [12] covers all algorithms with the outline of Algorithm 3. The initial μ search points may be sampled adaptively, i.e. the i-th sample may depend on the ranking of the first i-1 samples w.r. t. f. In each of the main iterations, this algorithm samples λ new search points from distributions that depend only on the current population P_t and the ranking of it. In each of these iterations, the λ offspring do not need to be independent of each other. However, it is required that all of the λ offspring are created before the fitness of any of them is evaluated.

Given a class \mathcal{F} of pseudo-Boolean functions, the complexity of an algorithm A for this class is the maximum expected number of fitness evaluations made by A, before it evaluates an optimal solution for the first time, where the maximum is taken over all fitness functions $f \in \mathcal{F}$. The $(\mu + \lambda)$ elitist black-box complexity of a class \mathcal{F} is the minimum complexity, taken over all $(\mu + \lambda)$ elitist black-box algorithms A with the outline of the Algorithm 3.

In the elitist $(\mu+\lambda)$ EA (which is a special case of Algorithm 3), a new offspring population P is created by selecting uniformly those from P_t and perturbing them with p_{mut} . The surviving population P_{t+1} of the next generation then composes of the μ best individuals among both parent and offspring populations $P_t \cup P$.

3 PROBLEMS WITH SPARSE OPTIMA AND DENSE FITNESS VALLEYS

We introduce a class of fitness landscapes SparseLocalOpt $_{\alpha,\varepsilon}$ which we claim separates elitist from non-elitist evolutionary algorithms. The class contains all functions which satisfy the following requirements. We first require that from any point in the search space, there must exist a not too long directed path to the global optimum, where consecutive steps on the path are near each other in the search space. Along any path, we distinguish between "deceptive regions" and "fitness valleys". Any region of the path with higher fitness than a later part of the path is called deceptive. Conversely, any region with lower fitness than an earlier part of the path is called a fitness valley. We only impose the constraint that deceptive regions must be sparse, while fitness valleys must be dense. Informally, a set is called dense if every member of the set has many neighbours in that set, and a set is called sparse if there are few set members in any direction. (In the following definitions, recall that $S_r(x)$ refers to the Hamming-sphere of radius r around bitstring x, as defined in Section 2.)

Definition 1. For $\alpha \in [0,1]$, a subset $C \subseteq \{0,1\}^n$ is called α -dense if $\forall x \in C$, $|S_1(x) \cap C| \geq \alpha n$.

DEFINITION 2. For $\varepsilon \in [0, 1]$, a subset $B \subseteq \{0, 1\}^n$ is ε -sparse if **(SP1)** $\forall x \in B, \forall r \in [n], |S_r(x) \cap B| \le \varepsilon \cdot \binom{n}{r}$, and **(SP2)** $\forall x \in \{0, 1\}^n \setminus B, \forall r \in [n], |S_r(x) \cap B| = O\left(\frac{1}{n}\binom{n}{r}\right)$.

To make the notion of deceptive regions and fitness valleys more precise, we formally define deceptive pairs.

DEFINITION 3. Given a function $f: \{0,1\}^n \to \mathbb{R}$ and a partition (A_1, \ldots, A_m) of $\{0,1\}^n$, a pair (A_i, A_j) is called f-deceptive if $1 \le i < j \le m$ and there are elements $x \in A_i$, $y \in A_j$ such that $f(x) \ge f(y)$.

We can now state the definition of the problem class.

DEFINITION 4. An objective function $f: \{0,1\}^n \to \mathbb{R}$ belongs to the problem class SparselocalOpt $_{\alpha,\varepsilon}$ if there exists a partition of $\{0,1\}^n$ into $m \in \text{poly}(n)$, subsets (A_1,\ldots,A_m) such that

- $A_m = \{x \in \{0,1\}^n \mid \forall y \in \{0,1\}^n, f(x) \ge f(y)\}$
- $\bullet \ \forall j \in [m-1], \forall x \in A_j, \exists y \in A_{\geq j+1} \ s.t. \ \mathsf{H}(x,y) = O(1),$

and if $(A_{i_1}, A_{j_i}), \ldots, (A_{i_u}, A_{j_u})$ are f-deceptive pairs then

- $\bigcup_{v=1}^{u} A_{i_v}$ is ε -sparse, and
- $A_{\geq i_n}$ is α -dense for all $v \in [u]$.

4 ELITIST BLACK-BOX ALGORITHMS

4.1 Elitist black-box complexity of BBFUNNEL

To prove that SparselocalOpt $_{\alpha, \varepsilon}$ has exponential elitist black-box complexity, we consider a sub-class BBFunnel (see Definition 5 and Theorem 8). The sub-class captures the same features of the problem Funnel introduced in [4], however it is a broader class. It is partly defined in terms of the functions Lo_z and Om (see Section 2).

DEFINITION 5. For any integers $1 \le u < v < w \le n$, and a simple path $p_1, p_2, \ldots, p_\ell \in \{0, 1\}^{v-u}$ of length $\ell \in \text{poly}(n)$ starting from $p_1 := 0^{v-u}$, let BBFunnel $\ell(x) := 0^{v-u}$

$$\begin{cases} \operatorname{Lo}_{y}(x) + \ell & \text{if } w < \operatorname{Lo}_{y}(x) \leq n \\ \operatorname{Lo}_{y}(x) & \text{if } v < \operatorname{Lo}_{y}(x) \leq w \\ i + w & \text{if } x = 1^{u} p_{i} 0^{n-v} \text{ where } i \in [\ell] \\ -n - \operatorname{OM}(x) & \text{if } \operatorname{Lo}_{y}(x) \geq u \text{ and } x \notin B \cup C \cup D \\ \operatorname{Lo}_{y}(x) & \text{if } \operatorname{OM}(x) \leq u \\ -\operatorname{OM}(x) & \text{if } x \notin A \cup B' \cup B \cup C \cup D \end{cases} \tag{A}$$

where a bitstring $z \in \{0, 1\}^{w-v}$, and $y := 1^u \cdot p_\ell \cdot z \cdot 1^{n-w}$.

To prove a worst-case runtime for any randomised, elitist black-box algorithm, we will apply Yao's principle.

Theorem 6 (Yao's Principle [37]). Let Π be a problem with a finite set I of input instances of fixed size permitting a finite set $\mathcal A$ of deterministic algorithms. Let I_p be a randomly chosen instance with a probability distribution p over I and let A_q be a randomly chosen algorithm with a probability distribution q over $\mathcal A$. Then $\min_{A\in\mathcal A} E\left[T(I_p,A)\right] \leq \max_{I\in I} E\left[T(I,A_q)\right]$, where T(I,A) denotes the running time of $A\in\mathcal A$ on $I\in I$.

We fix $\mathcal A$ to be the set of deterministic algorithms, which may become a realisation of the randomised elitist $(\mu + \lambda)$ black-box algorithms (see Algorithm 3). As pointed out by Doerr and Lengler [12], to account for the possibility that a deterministic elitist black-box algorithm can enter an infinite loop, it is necessary to extend the class $\mathcal A$ with algorithms that know the number of queries they have made. Clearly, lower bounds that hold in this more general class, also hold for the original class.

We define a random instance I_p from the class BBFunnel as follows. The bitstring z is chosen uniformly at random. Furthermore, the simple path p is constructed by the following randomised

algorithm (see [14]): Define a sequence R of $b=n^{2\delta}\mu$ points for any constant $\delta \in (0,1)$ and where m:=v-u and $r_0:=0^m$, and for all $i \leq b, r_{i+1}$ equals r_i except for one bit-position chosen uniformly at random. From this random sequence, we obtain a simple path where $p_0:=r_0$, and for $i \geq 0$, if $p_i=r_j$, then $p_{i+1}:=r_{k+1}$ where $k \geq j$ is the largest index where $r_j=r_k$. This construction ensures that p_0,\ldots,p_ℓ is a simple path, where ℓ is the (random) length of the induced path p. From Lemma 7, it follows that the path length satisfies $\ell \geq n^\delta \mu$ with probability $1-2^{-\Omega(n^\delta)}$. The following lemma is a variant of Theorem 8 in [14], but uses a different proof idea.

Lemma 7. For $d \le m/5$, and any bitstring $z \in \{0, 1\}^m$,

$$\Pr\left(H(z, r_{i+k}) \le d \mid H(z, r_i)\right) = 2^{d - H(z, r_i) - ck} + e^{-\Omega(m)},$$

where the random sequence $r_0, ..., r_b$, is distributed as described above, $i \in [0..b-1]$, $k \in [1..b-i]$, and c > 0 is a constant.

Lemma 7 can be used to prove that BBFunnel belongs to the class SparselocalOpt α, ε . Due to the page limit, the proof is omitted.

Theorem 8. For any constants $\sigma, \varepsilon \in (0, 1)$, with probability $1 - \sigma$, a function sampled from the class BBFunnel with $w \in \Theta(n), v - u \le n/2$ and $\ell \in \text{poly}(n)$ according to distribution I_p belongs to the problem class SparselocalOpt $_{\alpha,\varepsilon}$ with parameter $\alpha = 1 - w/n$.

In the following, let **A** be any deterministic, elitist $(\mu + \lambda)$ black box algorithm. All instances of BBFUNNEL define the fitness values in regions $A \cup A' \cup B'$ identically. So we can assume that an optimal deterministic algorithm **A** has hard coded the fitness values in these regions, and that it knows the starting point p_1 of the path in B.

In order to reach the optimum $y=1^u\cdot p_\ell\cdot z\cdot 1^{n-w}$, the algorithm must discover the end point p_ℓ of the random path and the hidden sub-string z. Lemma (9) implies that any black-box algorithm must explore large parts of the path before the end point p_ℓ is discovered.

Lemma 9. For each $t \in \mathbb{N}$, let M_t be the set of points visited up to step t of algorithm A. Assume that an instance of BBFunnel is sampled from the distribution I_p and the algorithm after step $t \leq e^{cd(n)}$ knows the path points p_0, \ldots, p_i but no further points on the path. Then $\Pr\left(p_{i+d(n)} \in M_{t+1}\right) = e^{-\Omega(d(n))}$, if c > 0 is small enough.

PROOF. For any $z \in M_{t+1}$, Lemma 7 with d = 0 implies

$$\Pr\left(z = p_{i+d(n)}\right) = \Pr\left(H(z, p_{i+d(n)}) \le 0\right)$$
$$= 2^{-H(z, p_i) - \Omega(d(n))} + e^{-\Omega(m)} = e^{-\Omega(d(n))}.$$

By a union bound over all $t + 1 \le e^{cd(n)} + 1$ elements in M_{t+1} ,

$$\Pr\left(p_{i+d(n)} \in M_{t+1}\right) \leq (t+1)e^{-\Omega(d(n))} = e^{-\Omega(d(n))}. \ \Box$$

Unless the algorithm knows the end point p_ℓ , the fitness function does not reveal any information about the hidden sub-string z. However, if the path length is at least $n^\delta \mu$, any elitist $(\mu + \lambda)$ EA must with high probability produce at least μ path points before the end point p_ℓ is discovered. From this point, the only way to discover the hidden sub-string z is to evaluate search points in region C. However, due to the elite nature of the algorithm, it is prevented from evaluating any search point. The only way for the algorithm to reach region D is to guess the bitstring z correctly.

Theorem 10. For any constants $\alpha, \varepsilon \in (0, 1)$ and $\mu, \lambda \in \text{poly}(n)$, the elitist $(\mu + \lambda)$ black-box complexity of SparselocalOpt $_{\alpha, \varepsilon}$ is $e^{\Omega(n)}$.

Proof. We apply Theorem 6 and consider the average case runtime of any deterministic elitist $(\mu + \lambda)$ black-box algorithm **A** wrt the following distribution I_p' over SparseLocalOpt $_{\alpha,\varepsilon}$.

We construct I_p' from the distribution I_p over BBFunnel with path length $b = \mu n^{2\delta} \in \operatorname{poly}(n)$, and parameters $w := (1-\alpha)n$, $v := (2/3)(1-\alpha)n$, and $u := \max(1/3(1-\alpha)n, v-n/2)$. Note that $m := v-u \le n/2$. Given a function f sampled according to distribution I_p , let F be the event that f has simple path length $\ell < n^\delta \mu$ or $f \notin \operatorname{SparseLocalOpt}_{\alpha,\varepsilon}$. By Theorem 8, Lemma 7 and a union bound, the probability of event F is less than $\sigma + 2^{-\Omega(n^\delta)}$ for any constant $\sigma \in (0,1)$. To sample from distribution I_p' , we sample f according to I_p , and return OneMax $\in \operatorname{SparseLocalOpt}_{1,0}$ if F occurs, and f otherwise.

When event F occurs, we use the lower bound $T(I_p', \mathbf{A}) \geq 0$. Otherwise, if event F does not occur, then by by Lemma 9, with probability $1 - e^{-\Omega(n^\delta)}$, algorithm \mathbf{A} must query at least $\ell/n^\delta \geq \mu$ of the points in the path region B before it obtains the final point p_ℓ . The fitness of these search points is higher than any search point in C, hence once the algorithm has obtained path point p_ℓ , the population contains only points in B. With μ elements in B, the algorithm cannot base any further decisions on the fitness values in region C. Hence, in order to reach region D, the algorithm must find the hidden sub-string z. The probability that z is found in any of the $e^{\Omega(n)}$ next queries made by the algorithm is exponentially small. Thus, if F does not occur, $T(I_D', \mathbf{A}) = e^{\Omega(n)}$.

By the law of total probability wrt F, $\min_{\mathbf{A} \in \mathcal{A}} T(I_p', \mathbf{A}) = e^{\Omega(n)}$, which by Yao's principle implies the theorem.

4.2 Elitist EAs with diversity mechanisms

It has been shown in [5] that on the \mathtt{JUMP}_k function, diversity mechanisms can improve the performance of $(\mu+1)$ GA. This base algorithm is outlined as Algorithm 4. As a corollary of Theorem 10, it holds that many of those mechanisms, denoted by the set L11 as they alter the tie-breaking rule in line 11, are not helpful to escape the local optimum of BBFunnel. Specifically, the set $L11 := \{duplicate elimination, duplicate minimisation, convex hull maximisation, Hamming distance maximisation, deterministic crowding\}.$

Theorem 11. There exists a BBFunnel function such that the expected optimisation time using any $(\mu+1)$ GA as in Algorithm 4 with $\mu = \text{poly}(n)$ and any parameters p_c and χ , and using one of the diversity mechanisms from the set L11, or none of them, is exponential.

5 NON-ELITIST ALGORITHMS

We now develop a set of sufficient conditions for non-elitist EAs using bitwise mutation to be efficient on SparseLocalOpt $_{\alpha,\varepsilon}$ (see Theorem 15). These conditions require that the selection mechanism has a non-linear β -function. As examples, we demonstrate that these conditions hold for Algorithm 1 (non-elitist EA) using 3-tournament selection (Corollary 16) and linear ranking selection (Corollary 17), and mutation rate close to the error threshold.

Algorithm 4 The $(\mu+1)$ GA on $\{0,1\}^n$ space.

Require: State space $\{0,1\}^n$, population size $\mu \in \mathbb{N}$, crossover probability p_c , and mutation parameter χ .

- 1: Initialise P_0 with μ individuals uniformly at random in $\{0,1\}^n$
- 2: **for** $t = 0, 1, 2, \ldots$ until termination condition met **do**
- Sample $x \sim \text{Unif}(P_t)$ and sample $p \sim \text{Unif}([0, 1])$ 3:
- 4: if $p \leq p_c$ then
- Sample $y \sim \text{Unif}(P_t)$. 5:
- Set $z \leftarrow$ by copying independently bit-by-bit either from x or from y with equal probability.
- 7:
- Set $z \leftarrow x$. 8:
- end if 9:
- Flip each bit of *z* with probability χ/n independently. 10:
- Set $P_{t+1} \leftarrow P_t \cup \{z\}$, then remove one element from P_{t+1} with the lowest fitness, breaking ties at random.
- 12: end for

Conditions for Efficiency of Non-Elitist EAs

The level-based theorem [3] is a tool for deriving upper bounds on the expected runtime of Algorithm 2. To derive sufficient conditions for the efficiency of non-linear EAs on SparseLocalOpt $_{\alpha,\varepsilon}$, we generalise the theorem by introducing a "deceptive region" B. The new conditions (G1) and (G2) are weakened (compared to those in [3]), and only required to hold if there few individuals in the deceptive region. A new condition (G0) requires that the number of deceptive individuals reduces in expectation by a $(1 - \delta)$ -factor if it is above some threshold $\psi_0\lambda$. This variant of the level-based theorem has been implicitly used before, including [10] and [2].

Theorem 12. Consider Algorithm 2 with population size λ . Given a partition $(A_1, ..., A_m)$ of X and a subset $B \subset X$, define $T := \min\{t\lambda \mid$ $|P_t \cap A_m| > 0$, where for all $t \in \mathbb{N}$, $P_t \in X^{\lambda}$ is the population in generation t. If there exist $z_1, \ldots, z_{m-1}, \delta \in (0, 1]$, and $\psi_0, \gamma_0 \in (0, 1)$ such that for any population $P \in X^{\lambda}$, $y \sim D(P)$, any $j \leq m-1$, any $\gamma \leq \gamma_0$, and any $\psi \geq \psi_0$,

- **(G0)** If $|P \cap B| \le \psi \lambda$ then $\Pr(y \in B) \le (1 \delta)\psi$,
- **(G1)** If $|P \cap B| \le \psi_0 \lambda$ and $|P \cap A_{>i}| \ge \gamma_0 \lambda$, then $\Pr\left(y \in A_{\geq j+1}\right) \geq z_j$,
- **(G2)** If $|P \cap B| \le \psi_0 \lambda$ and $|P \cap A_{\ge j}| \ge \gamma_0 \lambda$ and $|P \cap A_{\ge j+1}| \ge \gamma \lambda$,

then
$$\Pr\left(y \in A_{\geq j+1}\right) \geq (1+\delta)\gamma$$
,
(G3) $\lambda \geq \left(\frac{12}{\gamma_0 \delta^2}\right) \ln\left(\frac{300m}{z_* \delta^2}\right)$, where $z_* := \min_j z_j$,

then
$$E\left[T\right] \leq \frac{12\lambda}{\delta} + \left(\frac{96}{\delta^2}\right) \sum_{j=1}^{m-1} \left(\lambda \ln\left(\frac{6\delta\lambda}{4+z_j\delta\lambda}\right) + \frac{1}{z_j}\right)$$
.

PROOF. We call individuals in *B deceptive individuals*. To apply the level-based theorem [3], we first prove that the number of deceptive individuals quickly drops below $\psi_0 \lambda$. For any $t_0 \in \mathbb{N}$, define $Y_t := |P_{t_0+t} \cap B|$. Hence, by (G0), Y_{t+1} is stochastically dominated by the random variable $Z \sim Bin(\lambda, p_s)$ where $p_s :=$ $\max(\psi_0, Y_t/\lambda)(1-\delta)$. Then by a Chernoff bound (see e.g. [15]),

$$\Pr(Y_{t+1} \ge \max(\psi_0 \lambda, (1 - \delta/2) Y_t))$$

$$< \Pr(Z \ge (1 - \delta/2) \max(\psi_0 \lambda, Y_t))$$

$$= \Pr(Z \ge E[Z] (1 + \delta/(2(1 - \delta))))$$

$$\leq \exp\left(-\frac{\delta^2 \max(\psi_0 \lambda, Y_t)}{12(1-\delta)}\right) \leq e^{-\frac{\delta^2 \psi_0 \lambda}{12(1-\delta)}}. \quad (1$$

We now consider phases of length $\tau_1 + 2\tau_2$ generations, where

$$\tau_1 := \frac{\log(\psi_0)}{\log(1 - \delta/2)} \le \frac{(1 - \psi_0)(1 - \delta/2)}{\delta/2} < \frac{2}{\delta}.$$
 (2)

(Note that $\frac{x-1}{x} \le \ln(x)$ for all x > 0.) and

$$\tau_2 := \left(\frac{8}{\delta^2}\right) \sum_{j=1}^{m-1} \left(\ln \left(\frac{6\delta\lambda}{4 + z_j \delta\lambda} \right) + \frac{1}{z_j \lambda} \right) \tag{3}$$

$$\leq \frac{8m}{\delta^2} \left(\ln(6/z_*) + \frac{1}{\lambda z_*} \right) < \frac{8m}{\delta^2 z_*} \left(6 + \frac{1}{\lambda} \right) < \frac{146m}{3\delta^2 z_*} \tag{4}$$

where the last inequality applied $\lambda > 12$ which follows from condition (G3). Note that τ_2 is the expected time to reach level m in the original level-based theorem [3]. Now by Eqs. (1),(2),(4), condition (G3), and a union bound, with probability no more than

$$(\tau_1 + 2\tau_2)e^{-\frac{\delta^2\psi_0\lambda}{12(1-\delta)}} \le \left(\frac{2}{\delta} + \frac{292m}{3\delta^2 z_*}\right) \left(\frac{z_*\delta^2}{300m}\right) < \frac{1}{3},\tag{5}$$

after τ_1 generations of the phase, there are still $\lambda (1 - \delta/2)^{\tau_1} = \psi_0 \lambda$ deceptive individuals. By the Markov's inequality and the levelbased theorem [3], with probability no more than 1/2, the algorithm fails to reach level m after $2\tau_2$ generations of the phase. Inversely, by a union bound and Eq. (5), a phase is successful with probability 1 - 1/2 - 1/3 = 1/6. If the phase is unsuccessful, we can apply the same arguments to the next phase, since we have not assumed anything about the initial state of the population.

Hence, a successful phase occurs in expectation after at most 6 phases, i.e., $6(\tau_1 + 2\tau_2)$ generations. The theorem now follows because each generation produces λ individuals.

The following lemmas describe the behaviour of the bitwise mutation operator in dense and sparse regions of the search space.

LEMMA 13. If C is an α -dense set, then

$$\Pr(p_{\text{mut}}(x) \in C \mid x \in C) > (1 - \chi/n)^n (1 + \alpha \chi).$$
 (6)

Lemma 14. If B is ε -sparse with $\varepsilon=rac{
ho-(1-\chi/n)^n}{1-(1-\chi/n)^n}$, then

- $\Pr(p_{\text{mut}}(x) \in B \mid x \in B) \leq \rho$, and
- $Pr(p_{\text{mut}}(x) \in B \mid x \notin B) = O(1/n)$

Theorem 15. If there exist constants $\varepsilon, \psi_0, \gamma_0, \delta, \alpha \in (0, 1)$ such that Algorithm 1 with the bitwise mutation operator with rate χ , and a selection mechanism with β , and population size λ satisfying

(SM0)
$$\beta(0,\gamma) \leq \frac{\gamma}{\frac{\varepsilon}{1-\varepsilon} + \left(1 - \frac{\chi}{n}\right)^n}$$
 for all $\gamma \in [\psi_0, 1]$,
(SM2a) $\beta(0,\gamma) \geq \frac{\gamma(1+\delta)}{\left(1 - \frac{\chi}{n}\right)^n}$ for all $\gamma \in (0,\gamma_0]$,

(SM2a)
$$\beta(0,\gamma) \geq \frac{\gamma(1+\delta)}{(1-\frac{\chi}{2})^n}$$
 for all $\gamma \in (0,\gamma_0]$.

(SM2b)
$$\beta(\psi, \psi + \gamma) \ge \frac{\gamma(1+\delta)}{\left(1-\frac{\chi}{n}\right)^n(1+\alpha\chi)}$$
 for all $\gamma \in (0, \gamma_0], \psi \in [0, \psi_0],$

(SM3) $c \ln(n) \le \lambda \in \text{poly}(n)$ for a sufficiently large constant c,

then it has expected polynomial runtime on SparseLocalOpt $\alpha.\varepsilon$.

Proof. Consider any function f in the problem class, with an associated partition (A_1, \ldots, A_m) and f-deceptive pairs $(A_{i_1}, A_{i_1}), \ldots,$ (A_{i_u}, A_{j_u}) . We will apply Theorem 12 with respect to $B := \bigcup_{v=1}^u A_{j_v}$ which by the definition of the problem class is ε -sparse. Assume that

x = P(i) where $i \sim p_{sel}(P)$ and $y \sim p_{mut}(x)$. For any $\gamma \ge \psi_0$, we have by Lemma 14, condition (SM0), and the law of total probability

$$\Pr(y \in B) \le \Pr(x \in B) \Pr(y \in B \mid x \in B)$$
$$+ \Pr(x \notin B) \Pr(y \in B \mid x \notin B)$$
$$\le \beta(0, \gamma)\varepsilon + O(1/n) \le \gamma(1 - \varepsilon) + O(1/n).$$

Hence, for large n, condition (G0) is satisfied for any constant $\varepsilon' < \varepsilon$. Assume that $|P \cap B| \le \psi_0 \lambda$ and $|P \cap A_{\ge j}| \ge \gamma_0 \lambda$. Then, to produce an individual y in $A_{\ge j+1}$, it suffices to select an individual $x \in A_{\ge j}$, and flip d = O(1) bit-positions. Except for at most $\psi_0 \lambda$ individuals in B, the individuals in the set $A_{\ge j}$ have higher fitness than all other individuals. Thus, by condition (SM2b), we get

$$\begin{split} \Pr\left(y \in A_{\geq j+1}\right) &\geq \Pr\left(x \in A_{\geq j}\right) \Pr\left(y \in A_{\geq j+1} \mid x \in A_{\geq j}\right) \\ &\geq \beta(\psi_0, \psi_0 + \gamma_0) \left(\chi/n\right)^d \left(1 - \chi/n\right)^{n-d} \\ &\geq \frac{\gamma_0 \left(1 + \delta\right)}{\left(1 - \chi/n\right)^n \left(1 + \alpha \chi\right)} \left(\chi/n\right)^d \left(1 - \chi/n\right)^{n-d} =: z_j. \end{split}$$

Hence, condition (G1) is satisfied for the parameter $z_j = n^{-O(1)}$.

Assume that $|P\cap B| \leq \psi_0 \lambda$, $|P\cap A_{\geq j}| \geq \gamma_0 \lambda$ and $|P\cap A_{\geq j+1}| \geq \gamma \lambda$, then except for at most $\psi_0 \lambda$ individuals in B, the individuals in $A_{\geq j+1}$ have higher fitness than all others in P. We consider two cases. If A_{j+1} is a part of a deceptive pair, then by the problem definition, $A_{\geq j+1}$ is an α -sparse set. Lemma 13 and (SM2b) then imply

$$\Pr\left(y \in A_{\geq j+1}\right) \geq \Pr\left(x \in A_{\geq j+1}\right) \Pr\left(y \in A_{\geq j+1} \mid x \in A_{\geq j+1}\right)$$
$$\geq \beta(\psi_0, \psi_0 + \gamma) \left(1 - \chi/n\right)^n \left(1 + \alpha\chi\right) \geq \gamma(1 + \delta).$$

In case A_{j+1} is not part of a deceptive pair, the individuals in $A_{\geq j+1}$ are fitter than any other individual in the population, and to produce an individual in $A_{\geq j+1}$, it suffices to select a one in $A_{\geq j+1}$ and not flip any bits, which by (SM2a) occurs with probability

$$\Pr\left(y \in A_{\geq j+1}\right) \geq \Pr\left(x \in A_{\geq j+1}\right) \Pr\left(y = x\right)$$
$$\geq \beta(0, \gamma) \left(1 - \chi/n\right)^n \geq \gamma(1 + \delta).$$

Hence, condition (G2) of Theorem 12 is satisfied. Finally, (G3) follows immediately from (SM3) for some constant c since γ_0 and δ are constants and $m \in \text{poly}(n)$. All conditions are satisfied, thus the expected runtime on f is $O\left(\sum_{i=1}^{m-1} \lambda \ln(1/z_j) + 1/z_j\right) \in \text{poly}(n)$. \square

The following corollaries of Theorem 15 give example configurations where non-elitist EAs are efficient on SparseLocalOpt α, ε . The proofs are omitted due to the page limit. Future work should provide a more comprehensive analysis of the algorithmic configurations which satisfy the conditions of Theorem 15.

COROLLARY 16. Algorithm 1 with 3-tournament selection, population size $c \ln(n) \le \lambda \in \text{poly}(n)$ for a sufficiently large c, and mutation rate $\chi = 1.09812$ has polynomial worst case expected runtime on SparselocalOpt α, ε with $\alpha = 1/4$ and $\varepsilon = 7/10^5$.

COROLLARY 17. Algorithm 1 with linear ranking selection [24] for $\eta=2$, population size $c\ln(n)\leq \lambda\in \mathrm{poly}(n)$ for a sufficiently large c, and mutation rate $\chi=0.693146$ has polynomial worst case expected runtime on SparselocalOpt $_{\alpha,\varepsilon}$ with $\alpha=4/9$ and $\varepsilon=1/100$.

5.2 The (μ, λ) EA is inefficient

The (μ,λ) -selection mechanism has a linear β -function, and therefore does not satisfy the requirements imposed by Theorem 15. We will now show that the non-elitist (μ,λ) EA is inefficient on BBFunnel, thus by extension on the problem SparseLocalOpt_ ϵ,α . To achieve this, it suffices to prove that (μ,λ) EA requires exponential runtime with overwhelmingly high probability on a specific BBFunnel function, denoted as f in the rest of the section, where $z=1^{w-v}$ and the simple path is $(p_i)_{0\leq i\leq v-u}$ with $p_i=1^i0^{v-u-i}$.

Algorithm 1 has exponential runtime on any function with a unique optimum if the mutation rate χ exceeds $\ln(\alpha_0) + \sigma$ (called the error threshold), where α_0 is the reproductive rate of the algorithm, and for an arbitrarily small constant $\sigma \in (0,1)$ [22]. For the (μ,λ) EA, the error threshold occurs when $\chi \geq \ln(\lambda/\mu) + \sigma$. We therefore consider (μ,λ) EA for mutation rates $\chi \leq \ln(\lambda/\mu) - \sigma$, for any constant $\sigma \in (0,1)$. We will show that the population will quickly produce μ individuals in region B. From then on, all individuals will with high probability have a parent in B, and it will take exponential time to produce an offspring in D.

To simplify the derivations, we will only count generations where the population has an individual in region $\mathcal{Y} := A \cup B \cup C \cup D$. This will only under-estimate the runtime of the algorithm. Lemmas 18 and 19 show that it is unlikely that (μ, λ) EA optimises the *B*-region before the population contains μ individuals in *B*.

Lemma 18. If $\chi \leq \ln(\lambda/\mu) - \sigma$ for any constant $\sigma > 0$, then with probability $1 - t_0 e^{-\frac{\mu\sigma^2}{2(1+\sigma)}} - \lambda e^{-\Omega(n)}$, every population P_t of (μ, λ) EA, where $t \leq t_0$, contains at least μ individuals in $\mathcal{Y} := A \cup B \cup C \cup D$ of function f with $u \geq (1 + \varepsilon)n/2$ for any constant $\varepsilon > 0$.

PROOF. We prove the statement by induction on t. By a Chernoff bound and a union bound, all individuals in P_0 belong to A with probability $1-\lambda e^{-\Omega(n)}$. Assume that at least μ individuals in generation $t \leq t_0 - 1$ belong to region $\mathcal Y$. By the definition of the BBFunnel and of (μ,λ) -selection, any individual created in P_{t+1} has a parent in region $\mathcal Y$. So the probability that an offspring belongs to region $\mathcal Y$ is at least the probability that no bit is mutated, i.e., at least $(1-\chi/n)^n \geq e^{-\chi}(1-o(1)) \geq (\mu/\lambda)e^{\sigma}(1-o(1)) \geq (\mu/\lambda)(1+\sigma)$ where the last inequality follows from the fact that $e^{\chi} \geq 1 + \chi + \frac{\chi^2}{2}$ for any $\chi \geq 0$. Hence, the expected number of offspring in region $\mathcal Y$ is at least $\mu(1+\sigma)$, and by a Chernoff bound, the probability that there are less than μ such individuals is less than $e^{-\frac{\mu\sigma^2}{2(1+\sigma)}}$. The statement now follows by a union bound over t_0 generations. \square

Lemma 19. Let $u \geq (n/2)(1+\varepsilon)$ for any constant $\varepsilon > 0$, $v-u = \Omega(n)$ and define $\alpha := (v-u)/n$. Let P_t be the population in generation t of the (μ,λ) EA with $\lambda = \operatorname{poly}(n)$ and $\chi \leq \ln(\lambda/\mu) - \sigma$ for a constant $\sigma > 0$ on function f. Define $X_t := \max_{i \in [\lambda]} \operatorname{Lo}(P_t(i))$. For $T := \min\{t \in \mathbb{N} \mid X_t \geq v - \alpha n/3\}$, it holds $\Pr\left(T \leq n^{1-2\delta}\right) = e^{-\Omega(n^\delta)} + e^{-\frac{\mu\sigma^2}{2(1+\sigma)} + (1-2\delta)\ln(n)}$ for any constant $\delta \in (0,1/2)$.

PROOF. We say that *failure event 1* occurs if there exists a generation $t \leq n^{1-2\delta}$ where less than μ individuals in P_t belong to $\mathcal{Y} := A \cup B \cup C \cup D$. By Lemma 18, the probability of failure event 1 is less than $e^{-\frac{\mu\sigma^2}{2(1+\sigma)} + (1-2\delta)\ln n} + e^{-\Omega(n)}$ given that $\lambda = \text{poly}(n)$.

We say that *failure event 2* occurs if any individual in A is mutated into region $C \cup D$ within the first $n^{1-2\delta}$ generations. In a single step, such a mutation has probability of at most $\left(\frac{\chi}{n}\right)^{\alpha n} \leq 2^{-\Omega(n)}$ since at least αn 0-bits have to be flipped to 1. By a union bound, the failure probability of the event is no more than $\lambda n^{1-2\delta}2^{-\Omega(n)} = e^{-\Omega(n)}$.

We now assume that failure events 1 and 2 did not occur. Let t_1 be the first generation where the population contains an individual in region B. Firstly, we notice the probability that X_{t_1} exceeds $u+\alpha n/3$ is no more than $\lambda 2^{-\Omega(n)}=e^{-\Omega(n)}$ by a union bound since the easiest way to create an individual x in B with $\text{Lo}(x) \geq u+\alpha n/3$ from one in A still requires to flip at least $\alpha n/3$ specific bits. We call such excess failure event 3. Secondly, for a lower bound we can assume optimistically that for any generation $t \geq t_1$, some individual $x \in B$ with $\text{Lo}(x) = X_t$ is always picked as parent. Even with this, the probability of making a large improvement of n^δ in fitness within B is less than $(\chi/n)^{n^\delta} = 2^{-\Omega(n^\delta)}$ because n^δ specific bit-positions have to be flipped. We call any such mutation within the first $n^{1-2\delta}$ generations failure event 4 and by a union bound, its probability is no more than $\lambda n^{1-2\delta} 2^{-\Omega(n^\delta)} = e^{-\Omega(n^\delta)}$.

If failure events 1-4 do not occur, then $X_t - (u + \alpha n/3) \le X_t - X_{t_1} \le tn^{\delta} \le n^{1-\delta} < (1/3)\alpha n$ for all $t \le n^{1-2\delta}$ and sufficiently large n. The lemma follows by noting that $u + 2\alpha n/3 = v - \alpha n/3$.

We will estimate the expected "upgrade time" for the number of individuals X_t of (μ,λ) EA in $B \cup C \cup D$ by Lemma 20. If $\chi \le \ln(\lambda/\mu) - \sigma$, then the probability to produce an individual in $B \cup C \cup D$ is at least $(X_t/\mu) (1-\chi/n)^n \ge (X_t/\mu)e^{-\chi}(1-o(1)) \ge (X_t/\lambda)(1+\sigma)$. For a lower bound, we only count the latest sub-sequence of iterations where $X_t \ge 1$ with no preemptions. If $\mu \in \text{poly}(n)$, Lemma 20 implies that with probability $1-2^{-n^c}$ for a constant c>0, region $B \cup C \cup D$ takes over the population within at most $n^{1-2\delta}$ iterations.

LEMMA 20. Let $\mu, \lambda \in \mathbb{N}$ where $\mu \leq \lambda/(1+\delta)$ for some $\delta > 0$. Assume a stochastic process $(X_t)_{t \in \mathbb{N}}$ is defined by $X_t := \max(1, Z_t)$ where for all $t \in \mathbb{N}$ and $X_t < \mu, Z_t \sim \text{Bin}(\lambda, (1+\delta)X_{t-1}/\lambda)$, and $X_0 \in \mathbb{N}$. Let $T := \min\{t \mid X_t \geq \mu\}$, then $E[T] \leq (7/\delta^2) \ln(1 + (\delta/2)\mu)$. Furthermore $\Pr\left(T \geq r(14/\delta^2) \ln(1 + (\delta/2)\mu)\right) \leq 2^{-r}$ for any $r \in \mathbb{N}$.

PROOF. Let a distance function be $g(x):=\ln\left(\frac{1+(\delta/2)\mu}{1+(\delta/2)x}\right)$. By Lemma 6 from [3], the expected drift w.r. t. g is at least $\frac{\delta^2}{7}$. The upper bound on E[T] now follows by Theorem 2 [3], which is a variant of the additive drift theorem [18]. By Markov inequality, $X_t \geq \mu$ at least for one t in any phase of length 2E[T] with probability at least $\frac{1}{2}$. The tail bound follows by considering r phases. \square

We now show that the (μ, λ) EA is inefficient on BBFunnel.

Theorem 21. Let $\sigma, \varepsilon \in (0,1)$ be constants. The runtime T of (μ,λ) EA with population sizes $\lambda \in \operatorname{poly}(n), \, \mu \geq \frac{2(1+\sigma)}{\sigma^2} \ln(n), \, and$ mutation rate parameter $\chi \leq \ln(\lambda/\mu) - \sigma$ on BBFunnel with $v-u = \Omega(n), w-v = \Omega(n)$ and $u \geq (1+\varepsilon)n/2$ satisfies $\Pr(T \leq e^{c \min(\mu,n)}) \leq e^{-\Omega(\mu)} + e^{-\Omega(n^d)}$ for some constants c,d>0.

PROOF. It suffices to give a proof for function f. Let us note that

$$\mu \sigma^2 / (2(1+\sigma)) - (1-2\delta) \ln(n) = \Omega(\mu), \tag{7}$$

and count generations with some individuals in $\mathcal{Y} := A \cup B \cup C \cup D$.

We will prove a stronger statement that with probability $1 - e^{-\Omega(n^d)} - e^{-\Omega(\mu)}$, none of the search points produced during the first $e^{c \min(\mu, n)}$ generations are in region D for some constants c, d.

We let $phase\ 1$ be the first $n^{1-2\delta}$ generations. By Lemma 18 (failure probability $e^{-\Omega(\mu)}+e^{-\Omega(n)}$ by (7)), Lemma 19 (failure probability $e^{-\Omega(n^\delta)}+e^{-\Omega(\mu)}$), and Lemma 20 (failure probability $e^{-\Omega(n^c)}$) and a union bound, with probability at least $1-e^{-\Omega(\mu)}-e^{-\Omega(n^c)}$, by the end of Phase 1, the population consists of at least μ individuals in region B, and no individual has more than $v-(1/3)\alpha n$ leading 1-bits, where $\alpha:=(v-u)/n$. For a constant c>0 to be chosen later, let $phase\ 2$ to be the $e^{c\min(\mu,n)}$ generations after phase 1. A generation in phase 2 is said to fail if there are less than μ offspring in B, or there is a mutation from region B into region D.

Since the μ best individuals are in B, all offspring have parents in B. To create an offspring in B, it suffices to not flip any bit, i.e., with probability $(1-\chi/n)^n \geq (1-\sigma')e^{-\chi} \geq (\mu/\lambda)(1-\sigma')e^{\sigma}$ for any constant $\sigma' \in (0,1)$, if n is large enough. Choosing σ' so that $(1+\sigma')/(1-\sigma')=e^{\sigma}$, this probability is at least $(1+\sigma')(\mu/\lambda)$. By a Chernoff bound, the probability that the population has less than μ individuals from B in the next generation is $e^{-\Omega(\lambda)}=e^{-\Omega(\mu)}$. For those individuals to be the best of the population, no individual in D must be created. The probability of creating a D-individual by mutating a B-individual is $n^{-\Omega(n)}$. By a union bound, this event occurs with probability less than $\lambda \cdot n^{-\Omega(n)}=n^{-\Omega(n)}$ in any generation. By induction and a union bound, a failure occurs in phase 2 only with probability $e^{-\Omega(\mu)}+e^{-\Omega(n)}$.

6 CONCLUSION

We have presented SparselocalOpt $_{\alpha,\varepsilon}$, a general class of functions, in which depending on its parameters (α, ε) , the deceptive regions of the landscape are sparse while the fitness valleys are dense. By introducing a new version of the level-based theorem, we have deduced sufficient conditions for non-elitist EAs to have polynomial expected runtime on SparselocalOpt $_{\alpha,\varepsilon}$, and indicated some algorithms satisfying these conditions.

Conversely, we have shown that elitist black-box $(\mu + \lambda)$ EAs can meet a significant difficulty, i. e. get trapped in the local optima of functions from the sub-class BBFunnel. This result covers a large set of algorithms, including elitist genetic algorithms with different types of variation operators and even with the use of standard diversity mechanisms. We have shown unconditionally that the non-elitist (μ, λ) EA fails to optimise the BBFunnel problems in expected polynomial time, demonstrating an exponential performance differences between different non-elitist selection mechanisms.

In summary, the paper proves that non-elitist EAs can outperform elitist EAs by exponential factors on fitness landscapes with highly rugged and multi-modal structure. The results suggest that non-elitism should be considered more often when applying EAs to complex combinatorial optimisation problems.
